Abstract

D-branes in curved backgrounds can be treated with techniques of boundary conformal field theory. We discuss the influence of scalar condensates on such branes, i.e. perturbations of boundary conditions by marginal boundary operators. A general criterion is presented that guarantees a boundary perturbation to be truly marginal in all orders of perturbation theory. Our results on boundary deformations have several interesting applications which are sketched at the end of this note.

Talk given by V. Schomerus at the 32nd International Symposium Ahrenshoop on the Theory of Elementary Particles (Buckow, Germany, September 1998)

It was observed many years ago that low energy effective actions of (super-) string theories possess solitonic solutions. They are known as solitonic p -branes because of their localization along certain $p + 1$ -dimensional surfaces in the string-background. Later, Polchinski discovered a remarkable correspondence between such solitonic p -branes and Dp -branes, i.e. boundary conditions for open strings (for a review see [1]). This makes it possible to study branes through the ‘microscopic’ techniques of boundary conformal field theory. The latter are particularly effective in dealing with curved backgrounds and they have also been successfully applied to study non-BPS branes.

We consider conformal field theories on the upper half of the complex plane. Any such theory contains two different kinds of fields, namely *bulk fields* $\phi(z, \bar{z})$ (i.e. ‘closed string vertex operators’) which are defined for points in the interior $\text{Im } z > 0$ of the upper half-plane and *boundary fields* $\psi(x)$ (i.e. ‘open string vertex operators’) that are inserted along the boundary $\text{Im } z = 0$. Operator product expansions (OPEs) of the former specify the background of our string theory. Even if we do not allow for changes of these *bulk OPEs* there remains some freedom to choose different *boundary conditions*. Roughly speaking, this corresponds to the freedom of placing D-branes in a fixed background. A somewhat axiomatic characterization of the admissible boundary theories can be found e.g. in [2].

The problem of constructing boundary theories possesses some universal solutions in terms of the modular S -matrix, which were found by Cardy in [3]. They provide at least a finite set of boundary conformal field theories (D-branes) for a large class of backgrounds. On the other hand the relation with solitonic p -branes suggests the existence of continuous families of solutions. We shall explain below how such families may be recovered from a discrete set of boundary CFTs. The idea is to generate continuous deformations through perturbations with marginal boundary fields. Since the boundary operator content depends on the boundary condition, the number of possible deformations will depend on the boundary theory we start with.

Suppose we are given a set of correlation functions of some boundary con-

formal field theory. We want to perturb this initial theory by one of its boundary fields $\psi(x)$ according to the formal prescription

$$\begin{aligned} \langle \varphi_1(z_1, \bar{z}_1) \cdots \varphi_N(z_N, \bar{z}_N) \rangle_{\lambda\psi} &= Z^{-1} \cdot \langle I_{\lambda\psi} \varphi_1(z_1, \bar{z}_1) \cdots \varphi_N(z_N, \bar{z}_N) \rangle \\ &:= Z^{-1} \sum_n \frac{\lambda^n}{n!} \sum_{\sigma \in S_n} \int \cdots \int_{x_{\sigma(i)} < x_{\sigma(i+1)}} \frac{dx_1}{2\pi} \cdots \frac{dx_n}{2\pi} \langle \psi(x_{\sigma(1)}) \cdots \psi(x_{\sigma(n)}) \varphi_1 \cdots \varphi_N \rangle \end{aligned}$$

where λ is a real parameter. The symbol $I_{\lambda\psi}$ in the first line should be understood as a path ordered exponential of the perturbing operator,

$$I_{\lambda\psi} = P \exp\{\lambda S_\psi\} := P \exp\left\{\lambda \int_{-\infty}^{\infty} \psi(x) \frac{dx}{2\pi}\right\}. \quad (1)$$

The normalization Z is defined as the expectation value $Z \sim \langle I_{\lambda\psi} \rangle$. These expressions deal with deformations of bulk correlators only. If there are extra boundary fields present in the correlation function, the formulas need to be modified in an obvious fashion so that these boundary fields are included in the “path ordering”. Some particularly simple cases of this type will be discussed shortly. The path ordering is essential since correlations of boundary fields are only defined for an ordered set of insertion points along the real line. Their analytic continuation beyond this domain is not unique, in general.

To make sense of the above expressions (beyond the formal level), it is necessary to regularize the integrals (introducing UV- and IR-cutoffs) and to renormalize couplings and fields (for an introduction into bulk perturbations in 2D conformal field theories see e.g. [4]). IR divergences can be cured by putting the system into a “finite box”. On the other hand, we have to deal with UV divergences. So, let us introduce a UV cutoff ε such that the integrations are restricted to the region $|x_i - x_j| > \varepsilon$. Thereby, all integrals become UV-finite before we perform the limit $\varepsilon \rightarrow 0$.

In the following, we consider marginal boundary deformations where the conformal dimension h of the perturbing operator $\psi(x)$ is $h = 1$ so that there is a chance to stay at the conformal point for arbitrary values of λ . Of course, the dimension of the field ψ may decrease upon perturbation to values $h < 1$. In such cases, the perturbation with $\psi(x)$ is said to be *marginally relevant* and the perturbed theories are no longer scale invariant. Here we are interested in a condition which guarantees that $\psi(x)$ is *truly marginal*, i.e.

that the dimension of $\psi(x)$ stays at its initial value $h = 1$. Perturbations with truly marginal fields then lead to a one-parameter family of scale invariant theories.

It was shown in [2] that $\psi(x)$ is truly marginal provided that it is a self-local field of conformal dimension $h = 1$. The condition of self-locality requires ψ to obey

$$\psi(x) \psi(y) = \psi(y) \psi(x) \quad \text{for } x < y .$$

Here we assumed that the right hand side can be unambiguously defined by analytic continuation.

Let us briefly sketch the main idea behind this result. Because of its self-locality, $\psi(x)$ behaves like a connection in an abelian gauge theory so that we may employ the usual arguments to omit the path-ordering in our construction of the deformed correlators. Consequently, all integrals can be performed along the whole real axis. The cutoff ε together with the normalization by Z results in a small shift of the integration contour into the upper half-plane. Since these contour integrals do no longer depend on the cutoff, the limit $\varepsilon \rightarrow 0$ becomes trivial, i.e.

$$\begin{aligned} \langle \varphi_1(z_1, \bar{z}_1) \cdots \varphi_N(z_N, \bar{z}_N) \rangle_{\lambda\psi} &= \lim_{\varepsilon \rightarrow 0} \langle \varphi_1(z_1, \bar{z}_1) \cdots \varphi_N(z_N, \bar{z}_N) \rangle_{\lambda\psi}^{\varepsilon} \\ &= \sum_n \frac{\lambda^n}{n!} \int_{\gamma_1} \cdots \int_{\gamma_n} \frac{dx_1}{2\pi} \cdots \frac{dx_n}{2\pi} \langle \psi(x_1) \cdots \psi(x_n) \varphi_1 \cdots \varphi_N \rangle \end{aligned} \quad (2)$$

where γ_p is the straight line parallel to the real axis with $\text{Im } \gamma_p = i\varepsilon/p$. The expression on the right hand side is manifestly finite and is independent of ε as long as $\varepsilon < \min(\text{Im } z_i)$ where z_i denote the insertion points of bulk fields. Thus, the above formula allows us to construct the perturbed bulk correlators to all orders in perturbation theory.

The extension of these ideas to the deformation of correlators which involve boundary fields $\psi_1, \dots, \psi_N$ is straightforward *if and only if* the boundary fields $\psi_1, \dots, \psi_M$ are *local* with respect to the perturbing field ψ , i.e. iff

$$\psi(x) \psi_i(y) = \psi_i(y) \psi(x) \quad \text{for } x < y .$$

This usually places a strong constraint on boundary fields. But if it is satisfied, the (renormalized) correlation functions are again obtained through

contour integration formulas very similar to the eqs. (2) (see [2] for details). The explicit expressions imply in particular that *the conformal dimension of a boundary field $\psi'(x)$ is not changed upon deformation provided that ψ' is local with respect to ψ .*

The preceding statement has a number of nice consequences. First of all it certainly allows us to understand that non-locality is the only obstruction to true marginality. Indeed, with the choice $\psi' = \psi$ our result implies that the dimension of the perturbing self-local field ψ sticks to its initial value $h = 1$, i.e. that ψ is truly marginal.

Whenever we have several self-local boundary fields which are all local with respect to each other, they generate a multi-parameter deformation of the initial boundary theory. At first sight, this may seem to result in very trivial moduli spaces. However, it may happen that certain important properties of the boundary conformal field theory (e.g. the cluster property) break down at some finite value of the perturbation parameter λ [2]: Admissible deformations form a subspace $\Omega \subset \mathbb{R}^q$. The moduli space $\mathcal{M}$ we assign to our initial boundary condition is obtained from Ω upon identification of equivalent boundary theories, i.e. $\mathcal{M} = \Omega / \sim$. Here, equivalence must be tested by closed string exchange between different branes, as explained in [2].

Moduli spaces of $D0$ -branes are expected to probe the background geometry, i.e. they provide a way of recovering the background from the purely algebraic CFT description. A number of explicit examples are discussed in [2]. The resulting geometry, however, is not unique due to the freedom one has in declaring a given boundary condition a $D0$ -brane. Such choices may be understood as a consequence of T-duality (or mirror symmetry).

For boundary conditions in Gepner models [6] (i.e. D-branes on certain complete intersection Calabi Yau spaces), the moduli spaces $\mathcal{M}$ should come equipped with additional Kähler structures much as their cousins in algebraic geometry (see e.g. [5]) but this and other predictions of algebraic geometry remain to be investigated in more detail.

To state another corollary of our main result we consider N identical branes placed on top of each other. Within the CFT framework this means that we multiply all boundary fields with Chan-Paton matrices, as usual. Thus, instead of perturbing our theories with $\lambda\psi$, we generate perturbations by $\Lambda\psi$ where Λ is now some $N \times N$ matrix. A single self-local boundary field ψ can

be combined with several different matrix parameters Λ_i . This gives rise to a multi-parameter deformation provided that the matrices Λ_i commute,

$$[\Lambda_i, \Lambda_j] = 0 \quad . \quad (3)$$

We conclude that any self-local boundary field can generate an N-parameter deformation. In the case of D-branes on $\mathbb{R}^D$, this fact was first observed by Witten [7]. The N parameters are then interpreted as distances between the N branes in a fixed direction transverse to their world-volume. In the present context, equation (3) makes a rather general statement about flat directions of the brane's low energy effective action in curved backgrounds.

Deformations can have rather drastic effects on the geometry – and in particular on the ‘dimension’ – of branes [2]. For a compactified bosonic theory at the self-dual radius there exist boundary deformations that continuously deform Neumann- into Dirichlet-type boundary conditions. This phenomenon extends to other radii by means of radius-changing bulk deformations. Circle theories at rational radii possess additional tachyon condensates which are even capable of transforming Neumann-type branes into a superposition of Dirichlet-type branes and vice versa [2] (see also the recent work of Sen [8]).

Let us finally mention that our formula (2), and its appropriate generalization in the presence of boundary fields, provide a powerful tool in computing the deformed theory explicitly. They might be quite useful in studying certain bound states of D-branes. Related calculations by Sen (see [8] and references therein) were argued in [9] to support the idea of classifying D-branes through an appropriate K-theory of the background.
